

Copper Toxicosis in Bedlington Terriers

Copper Toxicosis is a potentially fatal condition among a small number of dog breeds, including the Bedlington Terrier.

The condition relates to an accumulation of copper in the liver which can cause liver disease and often leads to the animal's death at a young age.

Dogs can be tested and scored as 1:1 - Normal, 1:2 - a carrier though unaffected and 2:2 - an affected dog. Appropriate breeding ensures as far as possible that Normal bitches mated with Normal dogs have a low probability of producing higher scored CT puppies and this is a strategy adopted responsible and reputable breeders to remove or reduce the incidence of the condition in the line. Any dogs scored higher than 1 on either side will have a higher probability of producing CT affected puppies and therefore should never be used as breeding stock.

Owners should always have their dog tested, even if they are not going to be used for breeding. If the disease is detected early then there is a good chance of controlling it with medication and the correct diet.

Anyone looking for a puppy should ensure that the parents have been DNA tested and are 1:1 Normal. Never buy a puppy / dog through websites such as Gumtree or Pets4homes. ALWAYS ask to see evidence of clear DNA Certificates before committing. It is essential that you go through one of the Bedlington Terrier Puppy Registers - these are registers that only list reputable breeders who will ensure their lines are CT clear.

Bedlington Terrier Association - Claudia 07940 539282

BTRF recommend that all our new adopters carry out the simple DNA Test. Tests are relatively cheap (around £48) and can be obtained from [Animal DNA Diagnostics Ltd](#).
